Authors’ contributions
This work was carried out in collaboration between both authors. Author AA designed the study, wrote the protocol and supervised the work. Author MM managed the literature searches and edited the manuscript. Both authors read and approved the final manuscript.

ABSTRACT
Silage is a feed material that has been widely used in previous periods because it has an effective and useful role in feeding animals, saving in the cost of feed and increasing productivity. From the scientific-practical view it is considered as a feed material preserved in an anaerobic environment that ferments sugars and carbohydrates and thus produces organic acids (lactic, citric, and butyric acids), where organic acids work to keep feed material for long periods. A lot of practical experiments have been done to reach the best high-protein percentage mixture. This extension project was designed and implemented in 2017 by the Jordanian Ministry of Agriculture in collaboration with farmers and scientific research stations of the National Center for Agricultural Research. Ten feed mixtures were prepared with the necessary laboratory tests to determine the quality of the produced silage. Mixings of the fodders of alfalfa and corn were made with varying percentages of the two components so that the total does not exceed 100%. In addition, 5 mixtures were made of the first five mixtures, with a total of only 200%. After laboratory testing, the highest protein percentage was found to be 15.25% when fodders of corn mixed 100% with alfalfa by
100%. It is recommended to make this mixture for livestock breeders, especially cow breeders without adding molasses and industrial additives so that the highest yield is achieved, saving in the cost of feed and increasing productivity. This short scientific article aims at presenting a technical and scientific experiment for the production of the best silage by the highest protein level through the use of various mixtures of corn and alfalfa.

Keywords: Alfalfa; corn; fodders; Jordan; Silage.

1. INTRODUCTION

Silage is a feed material preserved in an anaerobic environment that ferments sugars and carbohydrates and thus produces organic acids (lactic, citric, and butyric acids), where organic acids work to keep feed material for long periods. Silage is produced from corn plants usually planted using fresh water or treated wastewater in an area characterized by high solar radiation intensity and thus ensuring high efficiency in photosynthesis and production of chlorophyll, sugars, and starches. Certain slicing mechanisms are used to cut the plants into small homogeneous pieces so that the fermentation process is highly efficient as well as to enhance digestion in livestock bodies. Natural silage is obtained from plants that are not sprayed with any chemical pesticides and filled with high pressure, helps to preserve and prevent damage for one year without any industrial additives. Modern technologies have created other sources of silage, such as alfalfa crop, molasses, liquid nutrients (supplements), and hay treated with urea.

Corn silage is one of the main forages fed to dairy cows in many countries around the globe [1]. Some of the reasons that corn silage is used include its high capacity for dry matter production, easy harvesting, and suitability for silo fermentation. These characteristics allow producers to reduce the use of feed concentrates, without impairing the physiology and performance of the animals [2]. Silage corn hybrids have predominantly been major silage forages for livestock in Jordan. The total count for dairy cows in Zarqa region is about 29,820 heads in 2016 [3].

Bittman, and Kowalenko [4] reported in the advanced silage corn management (a production guide for coastal British Columbia and the Pacific Northwest) on 2004 that the average protein content in corn silage was about (8.9%). Very close findings reported for Sudan-grass hay in 1994 by Harb et al. [5] of about (9%). However, a reference published by the extension services at Oregon State University in 1981 proved that the percentage of crude protein in the alfalfa silage was (17.1%) [6]. Similar findings of (17%) reported for alfalfa hay in 1994 by Harb et al. [5]. In addition, the nutritional value of sugar-cane molasses was (4%) of the crude protein [7]. Crude protein percentages for corn silage, alfalfa silage, and sugar-cane molasses are shown in Fig. 1.

![Crude Protein %](image_url)

**Fig. 1.** The crude protein percentage of corn silage, alfalfa silage, molasses and some mixtures, and compositions
Marina company implemented Mixtures and bales of corn silage with alfalfa [8]. The results showed that the percentage of crude protein is (15%) when mixing the corn silage with alfalfa hay (40%), while the mixing of corn silage with alfalfa hay of (50%), the crude protein content increased to (15.75%) Fig. 1.

Protein itself is an essential element of livestock nutrition, and there are many sources from which it can be derived. However, the term (crude protein) does not refer to or measure how much protein is present in forages. It is a chemical analysis of the forage that calculates the amount of nitrogen (N), which is the building block for amino acids that form proteins. This is then used to estimate the amount of true protein and non-protein nitrogen. To calculate it, total N is determined, then multiplied by 6.25 (there is 1 part N for every 6.25 parts protein in most forages). This number reflects a forage’s potential to provide protein that certain livestock requires [9].

This short scientific article aims at presenting a technical and scientific experiment for the production of the best silage by the highest crude protein level through the use of various mixtures of corn and alfalfa.

2. METHODOLOGY

Plates 1 to 4 show steps 1 to 4 of samples preparing for fermentation. The fodders of green corn and the alfalfa were brought and introduced to a device slicing machine which was used to cut the plants into small homogeneous pieces. The fodder mixtures were then prepared with a varying ratio in preparation for 50 days of fermentation (Table 1). Crude protein level test was carried out after fermentation in the research center forage lab.

3. RESULTS AND DISCUSSION

An experimental trial was carried out by mixing various mixtures of green raw feeds and exposing them to fermentation for 50 days. Laboratory tests were performed and results were shown in Table 1. The mean protein content of the 10 mixtures was (8.80%). Mixture number 6, which was 100% mixing of corn with alfalfa at the same percentage gave the highest percentage of crude protein percentage, which is (15.25%). The percent of increase for mixture number 6 on the average of all mixtures was about (73.39%).

*It is noted that the highest and best results were for alfalfa 100%; The best mix with respect to the crude protein percentage was mixture number 6, which represents mixing corn with alfalfa by 200%.

Vertical bars in Fig. 2 indicate the standard error of the mean (n=5). Each record in the figure is the average of five samples drawn from the original fermented sample.

Due to the lack of molasses and other materials that were often added to the feed material to be obtained before the process of manufacturing. The anaerobic bacteria worked on the analysis of cellulose and other materials to get energy and then converted to protein and that is why the high proportion of protein in the final product.

4. CONCLUSIONS

Fermented silage can be made by adding 100 percent of the fodders of green corn to 100 percent of the green alfalfa. The crude protein content after fermentation is high (about 15.25%) without the addition of molasses. This reduces the cost on the farmers while ensuring the required protein contents and high economic returns.

ACKNOWLEDGEMENTS

The authors would like to thank the National Center for Agricultural Research (NARC) for funding this extension study. Also special thanks to Dr. Nizar Haddad, Dr. Adeeb Abu Obeid, and Mr. Monther Judo’a for their support which appeared in this paper.
